

API Chaining

API chaining is a method used to create sequence of API calls where one output of the API is the input for the next API. It is about making many API requests in a row where each call is dependent to the other. Eg: POST /login → returns a token and that token is used in the header → GET /users.

Negative API testing

Negative API testing refers to testing what the api prints or what the output of the api will be with invalid, non-existing or missing values. It's main objective is to print the error code like 401 not found without crashing.

Error handling in APIs

API error handling is the process of identifying and responding to a specific error from an API response with the goal of resolving the issue as quickly as possible. API responses typically provide specific error codes and messages like “404 Not Found”.

Eg: A GET request is made to an API to retrieve details on a specific employee of a company. However, the employee doesn't exist in the company list. So, the possible output is a “Not Found” error message. The log from this request is added to the monitoring tool. The tool then parses the log, extracts key information (error code), and if configured—alerts the relevant stakeholders of the error. From there, developers can review the request to make sure it was formatted properly, analyze the error.

Negative API Scenarios

S.NO.	Scenario	Method	Status	Result
1	Create resource with a typo error	POST	400 Not Found	API returned '{}'
2	Send invalid data or missing quotation	POST	500 Internal Server Error	Error message saying unexpected token
3	Create non-existent token	POST	404 Not Found	404 Not Found
4	Invalid data type	POST	401 Unauthorized	API returned Bad Request
5	Invalid booking	GET	404 Not Found	API returns error saying 404 Not Found
